INTRODUCTION

Immunoo-oncology (IO) therapies have demonstrated effective and durable benefits in multiple cancer indications, but responses are variable. Discovery and validation of better biomarkers of treatment response, ability to modulate immune responses, selection of optimal drug combinations, and identification of IO targets are top priorities to maximize the clinical impacts of immunotherapy.

While the immune and tumor microenvironment have been well characterized in primary tumors, large-scale assessments in metastatic disease are lacking. Here, we conducted a multi-modal, pan-cancer analysis comparing immune states across primary and metastatic disease using a real-world database.

METHODS

Analysis was conducted using Tempus IO™, an immunoogenomics platform built on a large, real-world patient database.

Tempus IO comprises de-identified records with pre-computed immunophenotypes across dozens of cancer types, many treated with IO therapy. Somatic DNA alterations and whole-exome transcriptomes were modeled using the Tempus xT and xR NGS assays, respectively, with optimized probes for TCR/BCR profiling.

For assessment of immune cell fraction, TCR clonality, and IO biomarkers in solid tumors, 70K samples were selected from the Tempus Clinicogenomics Database. NSCLC cohorts were used to assess patient survival in relation to IO biomarkers and intratumoral TIL density from H&E images.

Imaging-based TIL density computation

H&E images are fed to two models, a tumor & stroma segmentation model and a lymphocyte classification model. Classified lymphocytes within the segmented areas are counted per mm² to give intra-tumoral and stromal TIL densities.

Acknowledgments: We thank Matthew Kace for data visualization guidelines and poster review.

SUMMARY

- A landscape, multi-modal comparison of tumor-immune states was performed on de-identified patient records.
- Bulk tumor RNA showed liver metastases had significantly lower immune infiltration, higher macrophage fraction, and lower TCR diversity compared to primary tumors and lung metastases.
- TIL quantification from digitized NSCLC H&E slides revealed a significant correlation between intratumoral TIL density and cytotoxic T-cell score, and confirmed lower intratumoral TIL density in liver metastases versus primary lung tumors.

RESULTS

Immune cell states vary across indications and primary versus metastatic sites

NGS-based measures of immune activity are associated with survival in IO-treated patients and vary across indications and primary versus metastatic sites

Intratumoral TIL density computed from NSCLC H&E images varies across tissue sites

Figure 1. Immune cell fraction estimates from RNA-seq and Shannon's entropy of TCR repertoire (higher values = more diverse repertoire) by tumor site. Asterisks indicate significant differences (pairwise Wilcoxon p < 0.001) in primary vs metastatic sites.

Intratumoral TIL density computed from NSCLC H&E images varies across tissue sites

Figure 2. (A) Cox proportional hazards (PH) regression of real-world overall survival in patients (n=1623) treated with first-line IO, stratified by cancer type and regimen class (IO monotherapy or IO + Chemotherapy). Each row represents a single stratified Cox PH model result for the selected RNA-based feature or TMB. (B) Biomarker distributions by cancer type and tumor site. Asterisks indicate significant differences (pairwise Wilcoxon p < 0.001) in primary vs metastatic sites.

Intratumoral TIL density computed from NSCLC H&E images varies across tissue sites

Figure 3. (A) Distribution of intra-tumoral TIL density in NSCLC by tumor site (N=104). (B) Cytotoxic T-cell score, representing the higher density of cytotoxic T cells in tumor areas. (C) Examples of cell classification model outputs for NSCLC in lung (primary) and liver (metastatic) tissues.
